Photosynthesis of the Amazon rainforest plays an important role in the regional and global carbon cycles, but, despite considerable in situ and space-based observations, it has been intensely debated whether there is a dry-season increase in greenness and photosynthesis of the moist tropical Amazonian forests. Solar-induced chlorophyll fluorescence (SIF), which is emitted by chlorophyll, has a strong positive linear relationship with photosynthesis at the canopy scale. Recent advancements have allowed us to observe SIF globally with Earth observation satellites. Here we show that forest SIF did not decrease in the early dry season and increased substantially in the late dry season and early part of wet season, using SIF data from the Tropospheric Monitoring Instrument (TROPOMI), which has unprecedented spatial resolution and near-daily global coverage. Using in situ CO2 eddy flux data, we also show that cloud cover rarely affects photosynthesis at TROPOMI’s midday overpass, a time when the forest canopy is most often light-saturated. The observed dry-season increases of forest SIF are not strongly affected by sun-sensor geometry, which was attributed as creating a pseudo dry-season green-up in the surface reflectance data. Our results provide strong evidence that greenness, SIF, and photosynthesis of the tropical Amazonian forest increase during the dry season.

It has been heavily debated among the remote sensing and ecological research communities whether there is a dry-season green-up and increase in photosynthesis of the moist tropical Amazon forest (1–5). The answer to this question has important implications for understanding Earth’s carbon fluxes and the impact of climate variability and climate change on those fluxes. However, a resolution to this debate has been delayed due to arguments that the geometry between the satellite sensors and the sun causes a pseudoseasonality in the reflectance data (4, 6).

Traditionally, spaceborne Earth surface reflectance data over the terrestrial biosphere have been used to calculate vegetation indices, which are useful for observing changes in canopy “greenness” and estimating chlorophyll content at large spatial scales (1, 7). However, vegetation indices do not provide direct information on the fate of sunlight absorbed by chlorophyll (absorbed photosynthetically active radiation [APAR];4), whose individual photons take one of 3 pathways: photosynthesis, heat dissipation, and chlorophyll fluorescence (8). Under favorable conditions, most APARatr is used for photosynthesis, and a small amount (≤2%) is emitted by chlorophyll as fluorescence in the red and far-red portion of the electromagnetic spectrum (~650 nm to 800 nm), which is created by the deexcitation of absorbed photons in all living plants (9).

Recently, quantification of the emission of solar-induced chlorophyll fluorescence (SIF) has become feasible from space, providing ample new opportunities to investigate the functioning of the photosynthetic machinery from remote sensing platforms (10–12). SIF retrievals require high spectral resolution and signal-to-noise ratio, and the only satellite instruments that have met these requirements were designed for atmospheric remote sensing, such as the Greenhouse Gases Observing Satellite, Global Ozone Monitoring Experiment 2, and Orbiting Carbon Observatory 2 (13–16). Although the global SIF datasets developed from these satellite observations have provided valuable insight into vegetation dynamics on Earth’s surface, their coarse spatial and temporal resolutions have not sufficiently resolved some important questions about the spatial distribution and temporal variability of SIF and photosynthesis on Earth. SIF is not a direct measure of photosynthesis, but satellite- and in situ-observed SIF has been shown to have a strong positive linear relationship with photosynthesis at the canopy scale (13, 15, 17), implying that changes in canopy SIF indicate changes in photosynthesis in the same direction (18, 19). The Tropospheric Monitoring Instrument (TROPOMI), a spectrometer onboard the Sentinel-5 Precursor satellite launched in October 2017 by the European Space Agency, enables a step change in SIF research, providing unprecedented high spatial and temporal resolution SIF observations that can address many of these important questions (20).

Here we report and analyze TROPOMI SIF data from March 2018 to June 2019 over the Amazon. TROPOMI’s high spatial and temporal resolution reveals previously unknown details on the spatial distribution of SIF in the Amazon (Fig. 1 A–C) and enables us to track SIF for forests and nonforests over time (Fig. 2 and SI Appendix, Figs. S1–S4). We show evidence that there is an overall dry-season increase in photosynthesis by Amazonian forests (Fig. 2A), where there was relatively little change in SIF in the early dry season (June through July), but a substantial increase in SIF in the late dry season (September through October) (Figs. 1A–C and 2A). Middle dry-season TROPOMI SIF in Fig. 1B, a point in time when the difference between forest and nonforest emergent fraction is greatest (Fig. S2A), is positively correlated with APAR across the region (Fig. S2B). This result validates the use of SIF as an indicator of photosynthesis in the Amazon (Fig. 2B), which provides strong evidence that forest SIF increases during the dry season.

The Amazon is the largest terrestrial contributor to global atmospheric carbon fluxes, but it has been debated whether photosynthesis in the Amazonian forest increases during the dry season. We now report new evidence that there is a dry-season increase in photosynthesis in the Amazon rainforest, using observations of solar-induced chlorophyll fluorescence from the Tropospheric Monitoring Instrument (TROPOMI), which has been shown to be a promising proxy of photosynthesis. The new findings point the way toward future research that addresses the implications of Amazonian seasonality on the global carbon cycle.

nonforest SIF is greatest, mimics the percentage of forest cover in each TROPOMI grid cell shown in Fig. 1F. The Amazon River and its tributaries in the northern part of the basin are also evident in Fig. 1A–C where surface water induces low SIF values. Wet-season SIF for seasonally moist forests (<2,000 mm mean annual precipitation [MAP]) was higher than SIF for moist forests (>2,000 mm MAP), which indicated that perhaps the productivity of seasonally moist forests was water-limited (Fig. 2). The ~2,000-mm MAP threshold has previously been found to determine whether water is a factor limiting photosynthesis in tropical forests (21).

For nonforest in the Amazon, SIF declined considerably in the early dry season (SI Appendix, Figs. S1 and S4), especially in the cropland region of central Bolivia and in the arc of deforestation in the Brazilian states of Acre, Rondônia, and Mato Grosso (Fig. 1D). In the late dry season, nonforest SIF continually increased. There were some hotspots where SIF decreased during the late dry season, notably in the Serra do Cachimbo Mountain region, the plains of the Brazilian state of Roraima, and the deforested areas in the vicinity of Santarém and Altamira (Fig. 1). In forests, the dry-season increase in SIF can be attributed to the loss of old leaves, the flushing of new leaves, and an increase in canopy chlorophyll content, which has been observed using in situ litterfall traps, tower-based time lapse photography, and satellite-based vegetation indices (1, 22, 23). For nonforest lands in the arc of deforestation, the decrease in SIF can be attributed to the...
harvest of crops and senescence of pasture, and the late dry-season increase in SIF is likely due to the early growth of pastures and crops such as maize, rice, sorghum, and soybean (24). At the basin scale, late dry-season SIF for moist and seasonally moist forest increased through October (Fig. 2C) despite decreased solar radiation in the canopy (PAR$_{TOC}$) (Fig. 2C) (25), which indicated that increased canopy chlorophyll content and photosynthesis drove dry-season increases in SIF and not PAR$_{TOC}$. TROPOMI SIF in the Amazon forest was remarkably consistent with in situ observations of increased dry-season photosynthesis in the moist tropical Amazon forest from the K83 CO$_2$ eddy flux tower (Fig. 2C), which is representative of dry-season observations of photosynthesis from the other moist tropical forest eddy flux tower sites in the Amazon (23).

Two previous studies claimed that the geometry between the satellite sensors and the sun affects the surface reflectance data, and thus the green-up during the dry season as shown by vegetation indices is a data artifact inducing false seasonality (4, 6). Is it possible that the seasonality of TROPOMI SIF in the Amazon is an artifact of sun-sensor geometry? TROPOMI has a wide swath of 2,600 km with daily, near-global coverage, and the satellite has a 16-d repeat cycle, meaning that, every 17 d, the satellite’s nadir and swath footprint are nearly identical. The phase angle of each sounding, which is the angle between the axes from the sounding to the sun and to TROPOMI’s sensor, varies along the swath. Each sounding along the swath also has a different footprint size, with the smallest footprint at nadir (3.5 × 7 km) and the largest at the edges of the swath (14 × 7 km).

SIF retrievals are sensitive to the phase angle, with higher SIF values at low phase angles when TROPOMI observes more-directly illuminated parts of the canopy (Fig. 3) (20). TROPOMI’s viewing angle for any location is most comparable every 17 d, when the footprint of the satellite track and local solar overpass time are nearly identical because of their vicinity to the equator. Thus, we investigated whether TROPOMI SIF has seasonality when viewing angle is held relatively constant by evaluating SIF for each satellite track and found that each track has the same seasonal pattern (SI Appendix, Figs. S1–S4). Although we are not able to account for changes in solar illumination with this strategy, we can assume that the viewing geometry alone does not alter the observed seasonality. One possible explanation for the observed seasonality in TROPOMI SIF is that the decreasing zenith angle of the sun in the dry season causes TROPOMI phase angles to likewise decrease (SI Appendix, Fig. S5). However, we found that SIF increased during the dry season across all phase angles and that the increase was larger than what could be explained by phase angle alone (Fig. 4 and SI Appendix, Figs. S6–S8). Furthermore, if phase angle was driving the observed seasonality in SIF, then we would expect SIF...
to decrease after the phase angles of the TROPOMI soundings reached their minimum. However, SIF increased for several weeks after TROPOMI phase angles began increasing and despite increased cloud cover (Fig. 2). We also found a significant and strong relationship between TROPOMI SIF and bidirectional reflectance distribution function (BRDF)-corrected vegetation index (EVI) from Moderate Resolution Imaging Spectroradiometer (MODIS) MCD43A4 for moist and seasonally moist forest ($R^2 = 0.82$ and 0.93, respectively), and between TROPOMI SIF for moist forest and the K83 tower site ($R^2 = 0.66$) (SI Appendix, Fig. S9).

The seasonality of TROPOMI SIF agrees with in situ seasonality of photosynthesis and MODIS EVI (Fig. 2A and B), but to what extent do incoming solar radiation and cloud cover affect canopy photosynthesis and spaceborne observations of SIF in the Amazon? The amount of photosynthetically active radiation reaching the top of the canopy (PAR$_{TOC}$) is determined by the difference between the amount of incoming PAR at the top of the atmosphere (PAR$_{TOA}$) from the sun and the amount of PAR reflected into space and absorbed by clouds, trace gases, aerosols, and particulate matter (APAR). Thus, seasonality in PAR$_{TOA}$ (length of day and solar angle) and APAR (mostly cloud cover/thickness) determine the amount and timing of instantaneous and daily PAR$_{TOC}$ (PAR$_{TOC} = PAR_{TOA} − ΔPAR$), which drives photosynthesis and serves as a phenological queue for tropical tree species (26).

Diurnally, there is a tight relationship between PAR$_{TOC}$ and photosynthesis in the morning and evening, as they rise and fall in tandem (27). At midday, the relationship between PAR$_{TOC}$ and photosynthesis decouples as the canopy becomes light-saturated (SI Appendix, Fig. S10). Using in situ data, we found that, during TROPOMI’s early afternoon overpass time of 12:45 PM to 2:30 PM local solar time (LST) over the Amazon (SI Appendix, Fig. S11), photosynthesis is nearly light-saturated (Fig. 5A–C) and ΔPAR rarely impacts photosynthesis (Fig. 5D–F). Dense clouds can block the emission of SIF into space, and TROPOMI soundings are prefiltered to remove soundings that are affected by high radiation levels due to cloud albedo and that have >80% cloud fraction. However, in situ data indicate that cloud cover rarely blocks enough solar irradiance at TROPOMI’s overpass time to induce light limitation of photosynthesis (Fig. 5). We cannot completely rule out that seasonal changes in cloud cover and optical thickness may affect SIF dynamics in the Amazon, but we did observe that the strongest increase in SIF occurred during the middle to late dry season despite reduced PAR$_{TOC}$ and increased ΔPAR and cloud fraction (SI Appendix, Fig. S12), which suggests that changes in cloud properties during the dry season have an insignificant effect on SIF retrievals. The seasonality of forest SIF was most similar to PAR$_{TOC}$ indicating that perhaps the timing of leaf flush in the forest is photosensitive to the length of the day and/or responsive to herbivory, which are not necessarily mutually exclusive (1, 28, 29).

In summary, the dry-season increase of TROPOMI SIF in the Amazon mimics the dry-season increase of photosynthesis as estimated from eddy flux data (23), in situ observations by phenological cameras of seasonal canopy senescence and leaf flush (22, 30), and BRDF-corrected, reflectance-based satellite observations (3, 11, 21, 31). Our results not only help resolve the debate over whether there is a dry-season increase in photosynthesis in moist tropical Amazon forest but also indicate that changes in photosynthesis during the dry season are largely driven by land cover type and changes in the forest canopy.

Materials and Methods

**TROPOMI Observations.** We used daily corrected ungridded TROPOMI SIF data for all data analysis (Fig. 1 and SI Appendix, Figs. S1–S4) and daily corrected gridded TROPOMI SIF data in 0.05° spatial resolution for visualization in Fig. 1 (20). Gridded (0.20°) and ungridded data are available at ftp://fluor.gps.caltech.edu/data/tropomi. It is also important to note that aerosols and clouds have different effects on SIF and reflected radiance at top-of-atmosphere (decreasing SIF, increasing reflectance), and cloud shadows reduce reflectance but not necessarily photosynthesis (Fig. 5), so any reflectance-based correction may introduce an

**Fig. 4.** TROPOMI SIF$_{daily}$ and SIF$_{instant}$ at different phase angles for the Amazon forest. Areas shaded in gray represent the early (E), middle (M), and late (L) dry seasons. The dashed line approximates when TROPOMI’s phase angles are lowest. These trends were also illustrated for moist and seasonally moist forest with greater than and less than 2,000-mm MAP and for nonforest in SI Appendix, Figs. S6–S8. Dates represent the first day of TROPOMI’s 16-d revisit cycle. Tick marks are every 16 d, and labels are every 32 d. The complete date range represented is 7 March 2018 to 29 June 2019.
Dry-season light and shade response of photosynthesis in the Amazon at TROPOMI overpass times (12:45 PM to 2:30 PM LST) at K83 eddy tower. Light-response curves of photosynthesis and PAR at the top of the canopy (PAR_{TOC}) in (A) early dry season, (B) mid dry season, and (C) late dry season. Shade-response curves of photosynthesis and the absorption and reflection of PAR incoming from the top of the atmosphere (\Delta PAR) before reaching the canopy in (D) early dry season, (E) mid dry season, and (F) late dry season.

In Situ Eddy Flux Observations and MODIS Data. In our analysis, we used Tier 1 FLUXNET2015 eddy flux data from the tower site K83 (BR-Sa3; Santarem Km83), located in seasonally moist tropical Amazon forest near −3.0180, −54.9714 (latitude/longitude), for the years 2000–2004 (32) (https://fluxnet.fluxdata.org/doi/FLUXNET2015/BR-Sa3). The seasonality in GPP, PAR_{TOC}, PAR_{IN}, and PAR_{OUT} at K83 (Fig. 2 A and B) was used in this manuscript as an example of observations from other eddy flux towers in the seasonally moist tropical Amazon forests (K34, K67, and CAX), which are in agreement and have been previously reported (23). Prior to plotting the light- and shade-response curves (Fig. 5), which are half-hourly data, we filtered the data to include only the highest-quality measured PAR (shortwave radiation incoming at the surface), thereby excluding gap-filled and estimates from the European Centre for Medium-Range Weather Forecasts (ECMWF) interim reanalysis (ERA-Interim). We also converted the local time of the eddy flux observations to LST. TROPOMI overpass times in the Amazon ranged from about 12:45 PM to 2:30 PM LST (31 Appendix, Fig. S11), so we plotted eddy covariance data whose 30-min timestamp range had midpoints between 1:00 PM and 2:15 PM LST.

We used BRDF corrected surface reflectance from the MODIS MCD43A4 data product (33) to calculate EVI. We calculated 16-d means of EVI from the daily data, which was available at 500-m spatial resolution, where EVI was calculated using bands 1 through 3,

\[
\text{EVI} = \frac{2.5 \times (b_2 - b_1)}{b_2 - 6 \times b_1 + 29.1}
\]

where b1 is the red band, b2 is the near-infrared band, and b3 is the blue band (34, 35).

Land Cover, Precipitation, and PAR Datasets. To determine forest and nonforest land cover, we used annual forest cover maps for 2008–2017 for the Amazon Basin with a spatial resolution of 500 m (36, 37). Only TROPOMI soundings that were in land cover map pixels that were consistently forest or nonforest were used in the data analysis. To prevent the inclusion of mixed water/land TROPOMI soundings from our analysis, we masked water from the TROPOMI data using the MOD44W Version 6 (38) water mask with a 7-km buffer. Implementing a similar buffer for forests to exclude TROPOMI soundings that were in land cover map pixels that were consistently forest or nonforest were used in the data analysis. To prevent the inclusion of mixed nonforest soundings due to the heterogeneity of nonforest area; thus we applied only a water mask to the TROPOMI data. Total annual and monthly precipitation (Fig. 1 G–I) was derived using the monthly, 0.25° Version 7 Tropical Rainfall Measuring Mission (TRMM) Multi-Satellite Precipitation Analysis (39). For 16-d precipitation means (Fig. 2 C), we used the TRMM Research Derived Daily Product (34). We calculated mean 16-d temperature and 16-d PAR values (Fig. 2B) using daily mean downward shortwave radiation at the surface (PAR_{TOC}) and the top (PAR_{TOC}) of the atmosphere, from the NCEP-DOE Reanalysis II data set (41). \Delta PAR was calculated as the difference between PAR_{TOC} and PAR_{TOC}.
